

Taking the whole current region removes the cone entirely, and a detector's angular acceptance does not spoil it: 99.7% of the current hemisphere's momentum lies inside $|\eta| < 3.5$. What does spoil it is a threshold on total momentum, which is not invariant under a boost along the axis. A transverse-momentum threshold is, and costs nothing. The $\gamma^* p$ region also holds four times the particles of the Breit hemisphere.
